Problem Analysis and Requirements

Chapter 2

Analysis of sound propagation in outdoor venue

2.1 Live venue sound challenges

This section explore the challenges of producing sound in an outdoor environmental. The challenge of producing a good sound experience for the audience highly depend on the calibration method and the atmosphere condition. It is well known that acoustically wave propagation is strongly affected by the inhomogeneous atmosphere doing the outdoor sound propagation. This inhomogeneous atmosphere shifts the calibration of the sound system which affect the intelligibility. section 2.1.1 gives an overview of the need of controled acoustics at live venue.

2.1.1 Acoustics as live venue

A outdoor Public Address System (PA) venue is an important concept today. It is used to address though, music or just entertainment where the number of audience is large. Sometimes more that 10.000 audience. The number of audience makes it difficult to address the opinion in an indoor venue and without speakers. Therefore an outdoor PA venue is a large area with a stage and speaker, which is designed to cover the audience area with a frequency spectrum that is linear in the audible frequency range. The speaker is often hanged in the side of the stage and is therefore only close to the audience in the front. Today the used speaker is called a line source array. It is an array of small wide speaker attached to each other to form a vertical line. Every speaker or a small group of the line source array can be controlled individual, both in sound coverage area angle and Sound Pressure Level (SPL). The benefit of the line source array modul design is that every speaker can be angled such that they cover it oven part of the audience area. The following Figure 2.1 shows a graphical illustration of the outdoor PA venue concept.

Figure 2.1: The figure illustrate the concept of outdoor PA venue

As it can be seen in the Figure 2.1 the distances from the one element in the line source array to the receiver is dependent on the receiver position. This indicate that the signal to every line source element have to be adjusted with respect to the coverage area. This is necessary because the wave amplitude decay with distances and is explained in section 2.2 in an ideal atmospheric condition. The adjustment is not as simple as just supply the upper speaker with more power. A sound wave is a mechanical movement of the particle in the air, which condensate and compression the air molecule so low pressure and high pressure respectavly. The movement of of the molecule depends on the medium, and in this report the medium is limited to air. The sound pressure is a local pressure divination of the instantiates atmospheric pressure. The atmospheric pressure therefore set a lover bound on the condensation but in theory there is no upper bound. To communicate the purpose without introducing distortion by the lower limit, the maximum amplification is therefore limited by the lover bound of the atmospheric pressure. Luckily the pressure near the ground is typically 101.325 kPa or a maximum pressure of 194 dB SPL . The movement of the particle in the air depends on the medium in the air. The medium in the air is not constand and varie over time with respect to wind, humanity and temperature. section 2.3 address the impact of homogeneous atmospheric effect on sound propagation. section 2.3 address the impact of inhomogeneous atmospheric effect on sound propagation.

2.2 Ideal geometric spreading loss

When a line source generates a sound wave, the wave field exhibits two fundamental difference spatially directive regions, near-field and far-field. In near-field, the wave propagates as a cylindrical wave wherein the far-field the wave propagates as a spherical wave. When the wave propagates as a cylindrical wave, the wave propagates only in the horizontal plane and therefore the attenuation is 3 dB SPL per doubling of distance. For a spherical wave propagation, the wave propagates in all direction, therefore the attenuation is 6 dB SPL per doubling of distance. The near field and far-field attenuation are based on non-absorption homogeneous atmospheric conditions. The border between the near-field and far-field depends on the hight of the array and the frequency. The distance can be calculated with Fresnel formula Equation 2.1, where the wavelength λ is approximated to $\frac{1}{3f}$ [Bauman et al., 2001]

$$d_B = \frac{3}{2} f \cdot H^2 \sqrt{1 - \frac{1}{(3f \cdot H)}} \quad (2.1)$$

Where:

d_B is the distance from the array to the end of near field	[m]
f is the frequency	[kHz]
H is the height of the array	[m]

In equation Equation 2.1 it can be calculated that less than 80 Hz radiate directly into spherical wave on the exit of the speaker. The following Figure 2.2 shows a horizontal cut of the near-field, far-field from a line source array.

Figure 2.2: The figure shows horizontal cut of a SPL radiation pattern of a line source array [Bauman et al., 2001].

2.3 Homogeneous atmospheric conditions

The aim of this section is to analyse the sound wave propagation in homogeneous atmospheric conditions. It is well known that the sound wave propagation is highly depending on the atmospheric conditions. The propagation depends on the atmospheric pressure, wind, temperature and humidity, where the two latter moreover is frequency dependent. The attenuation difference in frequency for temperature and humidity can be above 80 dB SPL [Cortel et al., 2017]. The following sections introduce a brief discussion of homogeneous atmospheric conditions effect on sound propagation.

2.3.1 Humanity and temperature impact

The temperature and humanity have two impacts on wave propagation, speed of sound and a lowpass effect. The following description starts with the latter.

Lowpass effect The effect of humanity and temperature act as a lowpass filter, where the low frequency remains without any additional attenuation. In other words, attenuation in the high frequency range per doubling of distance depends not only on the spreading loss but also on temperature and humanity. Therefore, for long distance, the atmospheric conditions have a high influence on the frequency spectrum delivered to the audience. Humanity and temperature attenuation are already well studied and standardised. Standard [ISO 9613-1:1993] gives an overview of calculating the frequency attenuation with respect to the distance, temperature and humanity. The article [Corteel et al., 2017] gives some examples of attenuation at a distance of 100 m. The article shows, if humanity increases proportional to the temperature, the lowpass effect is small. If the change in temperature and humanity is the opposite of each other, for example, the high temperature but dry, the attenuation in high frequency is significant. The following Figure 2.3 shows the worst-case scenario from [Corteel et al., 2017].

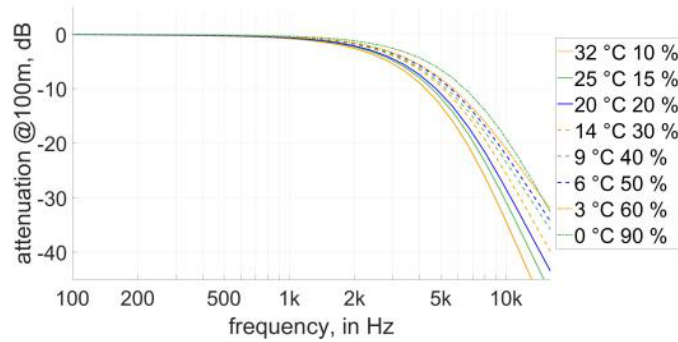

Figure 2.3: The graph shows the attenuation in dB with respect to frequency, humanity and temperature [Corteel et al., 2017].

Speed of sound The second consequence is the speed of sound. At temperature range from 0 °C to 40 °C the speed of sound with respect to humanity change is sparse and mostly depend on temperature change. At 0 % humanity the speed of sound only depend on the temperature. At humanity higher than 0 % the speed increase depends on temperature. The speed increase with respect to humanity depends on temperature. The higher the temperature is the higher the increase of the humanity is. At 0 °C the speed increases with approximately 0.8 m/s where for 30 °C speed increases with approximately 2.7 m/s [Wong and Embleton, 1985]. For temperature differences, the speed of sound increases approximately by 0.6 m/s for every increasing degree Celsius. The wave propagation speed starts at 331.5 m/s at

0 °C and 0 % humidity. The following ?? shows the speed of sound with respect to humidity and temperature.

2.3.2 Wind impact

The wind impact is complex and is not homogeneous with respect to sound source. The impact is depending on the angle of the wind direction with respect to the direction of sound propagation.

Parallel to sound propagation When the wind flows in the same direction as the sound wave propagation, the wind flow in m/s is an addition to the speed of sound. When the wind flows in the opposite direction it is a negative addition. In other cases, the influence is complex since the wind deflect the sound waves.

oblique- and crosswind The effect of oblique- and crosswind on sound wave propagation is rarely studied, and the effect seems to be unclear. Few author have addressed the problem in a simulation of traffic noise and by practical experience [de Oliveira, 2012], [Hornikx and Renterghem, 2017], [Ballou, 2008]. They claim that the crosswind effect refracts the wave in the wind direction. Furthermore, they claim that the effect is not linear in frequency. The author of [Ballou, 2008] indicates that the frequency dependency might be due to the directionality of the high frequency drivers.

2.3.3 Pressure impact

The influence of atmospheric pressure change is low compared to the effect of wind, humidity and temperature. The average attenuation from 4.0 kHz to 16.0 kHz with fixed temperature was 2 dB SPL while going from 54.02 kPa to 101.33 kPa. The atmospheric pressure then only have a negligibility influence on sound propagation and is generally not frequency dependent.

2.3.4 Ground absorption

2.3.5 Homogeneous speed equation

The following Equation 2.2 calculate the speed of sound based on homogeneous temperature and wind speed.

$$c = u \cdot \cos(\theta) + c_0 \sqrt{1 + t/t_0} \quad (2.2)$$

Where:

c	is the resulting speed of sound	[m/s]
u	is the speed of wind	[m/s]
c_0	is the speed of sound at 0 °C	[m/s]
t	is the temperature	[°C]
t_0	is the temperature at 0 °C (273.15)	[K]
θ	is the angle of wind with respect to the wave propagation	[°]

2.4 Inhomogeneous atmospheric conditions

The aim of this section is to analyse the sound wave propagation in inhomogeneous atmospheric conditions. In an inhomogeneous atmosphere, the pressure and speed is a function of position. By this fact, the modelling of a sound wave is very complex and depend on various variables such as temperature and wind speed. The following sections give a short introduction to the effect of inhomogeneous atmospheric conditions.

2.4.1 Atmospheric refraction

When the speed of the wind, the temperature and humidity is assumed to be homogeneous in the sound field, the sound is travelling in a straight path. Often this is not the case, the wind speed increases logarithmically with the height from the ground to the geostrophic wind [Yang, 2016] and the temperature and humidity are inhomogeneous. The geostrophic wind is founded from approximately 1 km above the ground [Association, 2003]. In such a situation the change of sound wave propagation is directly caused by the atmospheric temperature or wind. This often results in a curved path of the sound wave and is defined as atmospheric refraction. For small distances, the atmospheric refraction has a sparse effect on the sound travelling path, because the speed of sound is much faster than the speed of the wind and the temperature. Generally distance up to 100 m is often assumed to have no significant refraction effect [de Oliveira, 2012]. For distances larger than 100 m the refraction is assumed to have a significant influence, especially when the sound source and the receiver are close to the ground.

Temperature The refraction occurs because of the temperature change with respect to height along the day. The sun heats the ground, the and the concert area is full of audience. Therefore, the earth and audience radiate warm air, which makes the temperature at a low height warmer than the temperature at higher height. As explained in section 2.3.1, the speed of sound depends on the temperature and therefore, the speed of sound in this situation decays with respect to height and results in an upwards refraction. The following Figure 2.4 illustrates the phenomena where the temperature decays with respect to the height.

Figure 2.4: Wave refraction in inhomogeneous temperature

The sound refraction will be identically all around the source for a omnidirectional source with respect to temperature.

Wind With respect to the wind speed, a concert area is often a protected area with for example barrier, stage and building. This blockage slows down the wind speed close to the ground. Moreover, from nature itself, the wind speed is often logarithmically increased with respect to the height. When the wave is propagation in the same direction as the wind, the atmospheric refraction refracts the sound wave downwards. When the wave propagates against the wind, the atmospheric refraction refracts the sound wave upwards. The following Figure 2.5 shows the phenomena when the wave propagates against the wind.

Figure 2.5: Wave refraction in inhomogeneous wind

Due to the wind refraction effect, the sound propagates faster at the ground under the described condition. The consequence is a change of wave direction. This upwards refraction creates a shadow zone in the audience area [Yang, 2016]. In this shadow zone, the SPL is very low and the audience intelligibility is dramatically decreased. The following Figure 2.6 shows the phenomena.

Figure 2.6: The figure illustrate the shadow zone ocure from a upwards refraction. A line source speaker array contains of many couplet point sources. Every lowest sound path dashed line indicate the lower directional angle of one points source in the line source array.

As shown in Figure 2.6 the refraction is upwards when the wind flows in the opposite direction as the wave propagation. Behind the line array source, the refraction is downwards and is therefore different than for temperature refraction.

Oblique- and crosswind The effect of oblique- and crosswind on acoustical wave propagation in inhomogeneous atmospheric conditions are rarely studied. The author was not able to find any relevant paper on the subject.

Turbulent Turbulence is a atmospheric condition where the wind does not flow continuesly from one direction, but fluctuates from all directions. Fluctuation often occur in scales of hour, minutes and second where the latter is defined as turbulence. The turbulence wind flow is a chaotic and stochastic process by the nature. It can occur because of change in landscape for example bulding stage and blockage, but can also be a process of flow speed increase in the wind, which make the wind to refract on itself.

2.5 Atmospheric condition at a concert

A concert sound system is often calibrated in the middle of the day when the stage is finished. The concert often starts in the evening and goes along to the late evening...

2.6 Calibration of sound system

This section analyses the calibration method, which is used by a selection of some Danish sound company. By experience of the author, the hypothesis is that the sound system is calibrated in one point and the microphone is placed just in front of the Front Of House (FOH). The FOH is often a little tent, where the sound engineer controls the sound system. The tent is only open in the direction of the stage and reflection might occur from the tent ceiling to the calibration microphone.

2.7 Sound pressure level measurement doing the concert

Chapter 3

Summary of Problem Analysis

Three effect of atmospheric conditions have been observed on the analysis, pure attenuation, lowpass effect and refraction effect

Chapter 4

Problem statement

Based on the knowledge founded in chapter 2 and the conclusion drawn from ?? a problem statement can be made. For the rest of the project the following will be the focus.

research the effect of oblique- and crosswind on wave propagation.

4.1 Deimitation

The following deimitation is made for the search for a solution of .
